Database normalisation

- The learning objectives for this week are:
 - Knowing the purpose of database normalisation
 - Knowing what is a functional dependency, a partial dependency and a transitive dependency
 - Knowing how to identify functional dependencies in a relation or table
 - Knowing the different normal form rules
 - Knowing how to formally check if a relation is in the Boyce-Codd normal form (BCNF)
 - Knowing how to decompose a relation into smaller relations if it is not in BCNF

A substantial portion of these materials is derived from the work of Kari Silpiö. Any use, reproduction, or distribution of this content requires prior written permission from him.

Database normalisation

- Database normalisation is a formal technique of organizing data in a database in a way that
 redundancy and incosistency within the data is eliminated
- The objective of database normalisation is to ensure that:
 - Attributes with a close logical relationship (functional dependency) are found in the same
 relation
 - The relations do not display hidden data redundancy, which can cause update anomalies that violate database integrity
- The technique involves a set of normalisation rules that are defined as normal forms

Redundancy example

• Let's consider **redundancy problems** with the following Course_Enrolment relation rows:

course_code	instance_number	student_number	phone	enrolment_date
C001	1	10	1234	2025-04-01
C001	1	20	5555	2025-04-02
C002	3	30	8765	2025-04-01
C002	3	40	1414	2025-04-03
C002	3	10	1234	2025-04-07

Redundancy example

- The student 10 phone number is duplicated causing redundancy in the data
- While updating a phone number or inserting a new row, there's a risk of having multiple different phone numbers for the same student (inconsistency):

courseno	studentno	phone	enrolment_date
C001	10	<u>1234</u>	2025-04-01
C002	10	▲ 3338	2025-04-07

Database normalisation

- In a case of fixing an identified structural problem, normalisation involves decomposing a
 relation into less redundant (and smaller) relations without losing information
- When an ER model is well designed, the resulting correctly derived relations won't normally have such structural problems and they will meet the criteria of database normalisation
- Normalisation of candidate relations derived from ER diagrams is accomplished by analysing the functional dependencies (FDs) associated with those relations

Functional dependency

- Functional dependency (FD) describes the relationship between attributes in a relation
- With functional dependencies, we are interested in properties of the data that are true for all
 the time
- For example, if the **student number is unique**, the following property is true all the time:

 The surname for a student whose student number is "a12345" is "Smith"
- So, all the time it is true that there is only one surname for each student
- By contrast, the following property might to be true for a sample set of students, but it is not true for all the time:

There is exactly one student whose surname is "Smith"

Functional dependency

- A functional dependency occurs when attribute A in a relation uniquely determines attribute B
- In other words: for each value of A there is exactly one value of B and that holds all the time.
 This can be written as A → B
- The **determinant** of a functional dependency refers to the attribute, or group of attributes, on the **left-hand side** of the arrow. In $A \rightarrow B$, A is the determinant of B.
- On the right-hand side, there's the dependent. In A → B, B is the dependent of A.

Example of functional dependency

Let's suppose that each student has a unique student number. In the relation below, studentnumber uniquely determines surname and firstname. That is, studentnumber is the determinant of surname and firstname:

```
Student (<u>studentnumber</u>, surname, firstname)
```

- In this example, there are the following two functional dependencies:
 - studentnumber → surname
 - studentnumber → firstname

Example of functional dependency

Let's suppose the following table occurrence:

studentnumber	surname	firstname
a12345	Smith	John
a14444	Smith	Susan
a15555	Jones	Susan

The functional dependency studentnumber → surname guarantees that the query below (that uses an existing student number) returns exactly one surname and that holds all the time:

Example of functional dependency

- {A, B} → C means that A and B together uniquely determine C. For example, {course_code, implementation_number} → start_date
- A → B, C, D means that A uniquely determines B, C, and D, For example, course_code → course_name, language, credits

Identifying undesired data redundancy

- Relations that do not have undesired data redundancy, each determinant is a candidate key
 (an unique attribute that is suitable for being the primary key)
- In such case all arrows are arrows out of whole candidate keys (simple or composite key)
- Let's consider the following relation without data redundancy:

```
CourseOffering (<a href="coursecode">courseOffering</a> (<a href="coursecode">courseOffering</a> (<a href="coursecode">courseCode</a>, <a href="coursecode">offering</a>number, startdate, teachernumber)
```

- In this relations there's for example the following functional dependency:
 - {coursecode, offeringnumber} → startdate, teachernumber

Identifying undesired data redundancy

- Relations that have undesired data redundancy, there is a determinant that is not a candidate
 key
- In such case there is on arrow that is not an arrow out of a whole candidate key
- Let's consider the following relation with data redundancy:

```
CourseOffering (<u>coursecode</u>, <u>offeringnumber</u>, coursename, startdate, teachernumber, surname)
```

Identifying undesired data redundancy

- In this relations there's for example the following functional depedencies:
 - {coursecode, offeringnumber} → coursename, startdate, teachernumber,
 surname
 - X coursecode → coursename
 - teachernumber → surname
- In functional dependencies coursecode → coursename and teachernumber → surname,
 the determinants are not candidate keys
- With such functional dependencies, the relation has redundant data
- For example the teacher's surname is repeated unnecessarily, which can cause consistency issues for example when a teacher's surname is updated
- Instead, the teacher's information should be in a separate relation

Calculated attributes

- We should not include attributes in a relation that we can derive from other relations or calculate
- For example, let's suppose that the firm's total budget is the total of department budgets
- Therefore, totalbudget is a calculated attribute in the Firm relation
- The value of totalbudget should change whenever any department budget is changed in the firm
- From the data redundancy and integrity viewpoint, we have a problem here because total budget exists twice in the design:

```
Firm (<u>firmno</u>, firmname, totalbudget X)
Depertmant (<u>deptno</u>, deptname, deptbudget, firmno)
FK (firmno) REFERENCES Firm (firmno)
```

Calculated attributes

• We shouldn't have the *totalbudget* attribute in the *Firm* relation, instead we can calculate it with the following query:

```
SELECT SUM(deptbudget) as totalbudget FROM Department
WHERE firmno = 'a1122'
```

Different kind of functional dependencies

- Functional dependencies can be categorized in the following categories:
 - Non-trivial and trivial functional dependencies
 - Partial and full functional dependencies
 - Transitive and non-transitive functional dependencies

Non-trivial and trivial functional dependencies

- A → B is **trivial functional dependency** if B is a subset of A
- A → B is **non-trivial functional dependency** if B is not a subset of A
- Let's consider the *CourseOffering* relations:

```
CourseOffering (<u>coursecode</u>, <u>offeringno</u>, startdate)
```

- In the relation, {coursecode, offeringno} → startdate is a non-trivial functional dependency, because startdate is not a subset of {coursecode, offeringno}
- These, on the other are **trivial functional dependencies** of the relation:
 - {coursecode, offeringno} → coursecode
 - {coursecode, offeringno} → {coursecode, offeringno}
- In normalisation considerations we are only focusing on non-trivial functional dependencies

Normal forms

- Normal form refers to a set of normalisation rules that a database relation should follow inorder to be considered "normalized" and thus well-organized
- During the course we will cover the most common normal forms: first normal form (1NF),
 second normal form (2NF), third normal form (3NF) and Boyce-Codd normal form (BCNF)
- Each normal form from 1NF to BNCF adds more rules to the previous normal form
- For example, the 2NF includes all rules of the 1NF and additional rules
- The Boyce-Codd Normal Form (BCNF) is the strictest of these normal forms

First normal form (1NF)

- A relation is in the **first normal form** (1NF) if the following rules apply:
 - All attributes in a relation must have atomic values. No multi-valued attributes are allowed
 - A relation must have a primary key and all its attributes must be dependent on the primary
 key

Second normal form (2NF)

- A relation is in the **second normal form** (2NF) if the following rules apply:
 - Relation is in 1NF
 - Relation has no partial functional dependencies, meaning that there is no part of a candidate key that uniquely determines a non-candidate-key attribute
- Let's consider the following relation:

```
ClubMembership (<u>empno</u>, <u>clubno</u>, clubname, joindate)
```

- The relation has a partial functional dependency {empno, clubno} → clubname , because
 the functional dependency clubno → clubname exists in the relation
- That is, the relation is not in 2NF

Third normal form

- A relation is in the **third normal form** (3NF) if the following rules apply:
 - Relation is in 1NF
 - Relation has no functional dependency between two non-candidate-key attributes,
 meaning no non-candidate-key attribute is allowed to be transitively dependent on any
 candidate key within the relation
- Let's consider the following relation schema:

```
Employee (<a href="mailto:empno">empno</a>, surname, firstname, deptno, deptname)
```

- The relation has a transitive functional dependency deptno → deptname, causing deptname
 to be transitively dependent on empno via deptno
- That is, the relation is not in 3NF

Boyce-Codd Normal Form (BCNF)

- We simplify the rules of BCNF we will have the following limitations during the course:
 - We only focusing on non-trivial functional depdencies
 - Instead of including any superkeys in our analysis, we narrow the analysis to candidate keys
 - We do not allow any attribute that does not have a determinant within the relation
- With these limitations the BCNF has the following rules for a relation:
 - Each determinant is a candidate key
 - All attribute values are atomic (single values)
 - There is a determinant for each attribute that is not contained in a candidate key

Boyce-Codd Normal Form (BCNF)

Let's consider the following relation:

```
Teacher (<u>teacherno</u>, firstname, surname)
```

- teacherno → firstname, surname is the only functional depedency in the relation
- Z Each determinant is a candidate key
- All attribute values are atomic (single values)
- ✓ There is a determinant for each attribute that is not contained in a candidate key
- Thus, the relation is in BCNF

Boyce-Codd Normal Form (BCNF)

Let's consider the following relation:

```
CourseGrade (<a href="mailto:course_code">courseGrade</a> (<a href="mailto:course_code">course_code</a>, <a href="mailto:studentno">studentno</a>, <a href="mailto:firstname">firstname</a>, <a href="mailto:surname">grade</a>)
```

- studentno → firstname, surname is one of the **functional depedencies** in the relation
- studentno is not a candidate key in the relation (so each determinant is not a candidate key)
- Thus, the relation is not in BCNF

- To convert a non-BCNF relation to BCNF, we must decompose the relation in two steps
- Step 1: Find a **functional dependency** $X \rightarrow Y$ which violates the BCNF rule (find a determinant that is **not a candidate key**)
- Step 2: Split the original relation in two relations as follows:
 - Create a new relation with all attributes (for example both X and Y) from the dependency. X
 will be the primary key in the new relation
 - Remove Y attribute(s) from the original relation and leave X in the original relation to act as a foreign key.
- We repeat the steps above until all of our relations are in BCNF

Let's consider the following relation candidate:

```
CourseOffering (<a href="mailto:coursecode">coursecode</a>, <a href="mailto:offeringno">offeringno</a>, <a href="mailto:coursename">coursename</a>, <a href="mailto:startdate">startdate</a>, <a href="mailto:teacherno">teacherno</a>, <a href="mailto:surname">surname</a>, <a href="mailto:firstname">firstname</a>)
```

- In the first step, we identify the functional dependencies:
 - {coursecode, offeringno} → coursename, startdate, teacherno, surname,
 firstname
 - coursecode → coursename
 - teacherno → surname, firstname
- Then, we identify functional dependencies where the determinant is not a candidate key
- There's two such cases: coursecode → coursename and teacherno → surname, firstname

- In the second step, to solve these two cases we split the original relation two times
- With coursecode → coursename we create a new relation Course with attributes
 coursecode and coursename
- The determinant, the coursecode will be the primary key for the relation. We'll get the following relation:

```
Course (<u>coursecode</u>, coursename)
```

• Finally, we remove the coursename from the CourseOffering relation and leave coursecode as a foreign key:

```
CourseOffering (<u>coursecode</u>, <u>offeringno</u>,
startdate, teacherno, surname, firstname)
FK (coursecode) REFERENCES Course(coursecode)
```

■ We will repeat the same process with teacherno → surname, firstname and the final relations are the following:

```
Course (<a href="mailto:coursecode">coursecode</a>, coursename)
Teacher (<a href="mailto:teacherno">teacherno</a>, surname, firstname)
CourseOffering (<a href="mailto:coursecode">coursecode</a>, offeringno, startdate, teacherno)

FK (<a href="mailto:coursecode">coursecode</a>)
FK (<a href="mailto:teacherno">teacher(<a href="mailto:coursecode">teacherno</a>)

FK (<a href="mailto:teacherno">teacher(<a href="mailto:teacherno">teacherno</a>)
```

- Finally, we check the decomposed relations
- In each relation above each determinant is a candidate key and each attribute non-candidatekey attribute has a determinant
- Therefore, the relations are in BCNF and we have successfully removed all the undesired redundancy from the design

Summary

- Database normalisation is a formal technique of organizing data in a database in a way that
 redundancy and incosistency within the data is eliminated
- We analyze a set normalisation rules to determine if a relation is in a certain normal form (1NF, 2NF, 3NF, BCNF)
- Normalisation rules determine what kind functional dependencies the relation can have
- We can turn a non-BCNF relation into BCNF relations by decomposing the relation
